Introduction

This document describes how to use Cisco IOS® software to troubleshoot issues with Spanning Tree Protocol (STP).

Prerequisites

Requirements

Cisco recommends that you have knowledge of these topics:

- Various Spanning Tree types and how to configure them. Refer to [Configuring STP and IEEE 802.1s MST](#) for more information.
- Various Spanning Tree features and how to configure them. Refer to [Configuring STP Features](#) for more information.

Components Used

The information in this document is based on these software and hardware versions:

- Catalyst 6500 with Supervisor 2 engine
- Cisco IOS Software Release 12.1(13)E

The information in this document was created from the devices in a specific lab environment. All of the devices used in this document started with a cleared (default) configuration. If your network is live, ensure that you understand the potential impact of any command.

Conventions

Refer to [Cisco Technical Tips Conventions](#) for more information on document conventions.

Background Information

There are specific commands which apply to the Catalyst 6500/6000 only; however, you can apply most of the principles to any Cisco Catalyst switch that runs Cisco IOS software.

Issues with most STPs have these three problems:

- Forwarding loops.
- Excessive flooding due to a high rate of STP Topology Changes (TC).
- Issues related to convergence time.

Because a bridge has no mechanism to track whether a certain packet is forwarded multiple times (for example, an IP Time to Live [TTL]) or is used to discard traffic that circulates for too long in the network. Only one path can exist between two devices in the same Layer 2 (L2) domain.

The purpose of STP is to block redundant ports based on an STP algorithm, and to resolve redundant physical topology into a tree-like topology. A forwarding loop (such as an STP loop) occurs when no port in a redundant topology is blocked, and traffic is forwarded in circles indefinitely.

Once the forwarding loop starts, it congests the lowest-bandwidth links along its path. If all the links are of the same bandwidth, all links are congested. This congestion causes packet loss and leads to a network down situation in the affected L2 domain.

With excessive flooding, the symptoms are not as apparent. Slow links can become congested by flooded traffic, and devices or users behind these congested links can experience slowness, or total loss of connectivity.

Causes of STP Failures

STP makes certain assumptions about its operational environment. These are the assumptions most relevant to this document:

- Each link between the two bridges is bidirectional. This means that, if A directly connects to B, then A receives what B has sent and B receives what A has sent, as long as the link is up between them.
- Each bridge that runs STP is able to regularly receive, process, and transmit STP Bridge Protocol Data Units (BPDUs), also known as STP packets.

While these assumptions appear logical and obvious, there are situations where they are not met. Most of these situations involve a type of hardware issue; however, software defects can also lead to STP failures. Various hardware failures, misconfigurations, connection problems cause the majority of STP failures, while software failures account for the minority. STP failures can also occur due to unnecessary additional connections that exist between the switches. VLANs go into a down state because of these additional connections. To resolve this problem, remove all of the unwanted connections between the switches.

When one of these assumptions is not met, one or more bridges cannot receive or process the BPDUs. This means that the bridge (or bridges) is not discover the network topology. Without knowledge of the correct topology, the switch cannot block the loops. Therefore, the flooded traffic circulates over the looped topology, consumes all bandwidth, and brings down the network.

Examples of why the switches cannot receive BPDUs include bad transceivers or Gigabit Interface Converters (GBICs), cable issues, or hardware failures on the port, the line card, or the Supervisor engine. One frequent reason for STP failures is a unidirectional link between the bridges. In such a condition, one bridge sends BPDUs, but the downstream bridge never receives them. STP processing can also be disrupted by an overloaded CPU (99 percent or more) because the switch is unable to process received BPDUs. BPDUs can be corrupted along the path from one bridge to the other, which also prevents proper STP behavior.

Aside from the forwarding loops, when no ports are blocked, there are situations when only certain packets are incorrectly forwarded through the ports that block traffic. In most cases, this is caused by software issues. Such behavior can cause slow-loops. This means some packets are looped, but the majority of the traffic is still flows through the network, because the links are not congested.

Troubleshoot Forwarding Loops

Forwarding loops vary greatly both in their origin (cause) and effect. Due to the wide variety of issues that can affect STP, this document can only provide general guidelines about how to troubleshoot forwarding loops.

Before you start to troubleshoot, you need this information:

- An actual topology diagram that details all of the switches and bridges.
- Their corresponding port numbers (interconnected).
- STP configuration details, such as which switch is the root and backup root, which links have a non-default cost or priority, and the location of the ports that block traffic.

1. Identify the Loop

When a forwarding loop has developed in the network, the usual symptoms are:

- Loss of connectivity to, from, and through affected network regions.
- High CPU utilization on routers connected to affected segments or VLANs that can lead to various symptoms, such as routing protocol neighbor flapping or Hot Standby Router Protocol (HSRP) active router flapping.
- High link utilization (often 100 percent).
- High switch backplane utilization (compared to the baseline utilization).
- Syslog messages that indicate packet looping in the network (for example HSRP duplicate IP address messages).
- Syslog messages that indicate constant address relearning or MAC address flapping messages.
- The number of outputs drops on many interfaces increases.

Any of these reasons alone can indicate different issues (or no issue at all). However, when many of these are observed at the same time, it is highly probable that a forwarding loop has developed in the network. The fastest way to verify this is to check the switch backplane traffic utilization:

```
<#root>
cat#
show catalyst6000 traffic-meter

traffic meter = 13%
Never cleared

peak = 14%
reached at 12:08:57 CET Fri Oct 4 2002
```

 **Note:** The Catalyst 4000 with Cisco IOS software does not currently support this command.

If the current traffic level is excessive or if the baseline level is not known, check whether the peak level has been achieved recently and whether it is close to the current traffic level. For example, if the peak traffic level is 15 percent and it was reached just two minutes ago and current traffic level is 14 percent, that means the switch has an unusually high load. If the traffic load is at a normal level, then that probably means that there is either no loop or that this device is not involved in the loop. However, it still could be involved in a slow loop.

2. Discover the Topology (Scope) of the Loop

Once it has been established that the reason for the network outage is a forwarding loop, the highest priority is to stop the loop and restore the network operation.

To stop the loop, you must know which ports participate in the loop: look at the ports with the highest link utilization (packets per second). The **show interface** Cisco IOS software command displays the utilization for each interface.

To display only the utilization information and the interface name (for a quick analysis), filter the regular expression output with the Cisco IOS software. Issue the **show interface | include line | \/\sec** command to display only the packet per second statistics and the interface name:

```
<#root>
cat#
show interface | include line | \/\sec

GigabitEthernet2/1 is up, line protocol is down
  5 minute input rate 0 bits/sec, 0 packets/sec
  5 minute output rate 0 bits/sec, 0 packets/sec
GigabitEthernet2/2 is up, line protocol is down
  5 minute input rate 0 bits/sec, 0 packets/sec
  5 minute output rate 0 bits/sec, 0 packets/sec

GigabitEthernet2/3 is up, line protocol is up
  5 minute input rate 99765230 bits/sec, 24912 packets/sec

  5 minute output rate 0 bits/sec, 0 packets/sec

GigabitEthernet2/4 is up, line protocol is up

  5 minute input rate 1000 bits/sec, 27 packets/sec

  5 minute output rate 101002134 bits/sec, 25043 packets/sec

GigabitEthernet2/5 is administratively down, line protocol is down
  5 minute input rate 0 bits/sec, 0 packets/sec
  5 minute output rate 0 bits/sec, 0 packets/sec
GigabitEthernet2/6 is administratively down, line protocol is down
  5 minute input rate 0 bits/sec, 0 packets/sec
  5 minute output rate 0 bits/sec, 0 packets/sec
GigabitEthernet2/7 is up, line protocol is down
  5 minute input rate 0 bits/sec, 0 packets/sec
  5 minute output rate 0 bits/sec, 0 packets/sec

GigabitEthernet2/8 is up, line protocol is up

  5 minute input rate 2000 bits/sec, 41 packets/sec

  5 minute output rate 99552940 bits/sec, 24892 packets/sec
```

Pay attention to the interfaces with the highest link utilization. In this example, these are interfaces g2/3, g2/4, and g2/8; they are the ports that participate in the loop.

3. Break the Loop

To break the loop, you must shut down or disconnect the involved ports. It is particularly important not only to stop the loop but also to find and fix the root cause of the loop. It is relatively easier to break the loop

Note: You do not have to shut down or disconnect all ports at the same time. You can shut them down one at a time. It is better to shut down ports at the aggregation point affected by the loop, such as a distribution or core switch. If you shut down all of the ports at once and enable or reconnect them one-by-one, it does not work; the loop is stopped and cannot start immediately after the faulty port is reconnected. Therefore, it is difficult to correlate failure to any particular port.

Note: To break the loop, it is recommended that you collect information before you reboot the switches. Otherwise, subsequent root cause analysis is difficult. After you disable or disconnect each port, you must check whether the switch backplane utilization is back to a normal level.

Note: Keep in mind that ports do not sustain the loop but are flooding the traffic that arrives with the loop. When you shut down such flooding ports, you only reduce backplane utilization a small amount, but you do not stop the loop.

In the next example topology, the loop is between switches A, B, and D. Therefore, links AB, AD, and BD are sustained. If you shut down any of these links, you stop the loop. Links AC, AE, BC, and BE are just flooding traffic that arrives with the loop.

Looped and Flooded Traffic

After the support port is shut down, backplane utilization goes down to a normal value. You need to know which port's shutdown brought the backplane utilization (and other ports' utilization) to a normal level. At this point, the loop is stopped, and the network operation improves; however, because the original cause of the loop was not fixed, there still are other issues.

4. Find and Fix the Cause of the Loop

Once the loop is stopped, you need to determine the reason the loop began. This is the difficult part of the

process because the reasons can vary. It is also difficult to formalize an exact procedure which works in every case.

Guidelines:

- Investigate the topology diagram to find a redundant path. This includes the support port found in the previous step that comes back to the same switch (the path packets talked during the loop). In the previous example topology, this path is AD-DB-BA.
- For every switch on the redundant path, check whether the switch knows the correct STP root.

All switches in an L2 network must agree on a common STP root. It is a clear symptom of problems when bridges consistently display a different ID for the STP root in a particular VLAN or STP instance. Issue the **show spanning-tree vlan vlan-id** command to display the root bridge ID for a given VLAN:

```
<#root>
cat#
show spanning-tree vlan 333

MST03
Spanning tree enabled protocol mstp

Root ID    Priority    32771
  Address   0050.14bb.6000
  Cost      20000
  Port      136 (GigabitEthernet3/8)
  Hello Time 2 sec  Max Age 20 sec  Forward Delay 15 sec

  Bridge ID Priority    32771 (priority 32768 sys-id-ext 3)
  Address   00d0.003f.8800
  Hello Time 2 sec  Max Age 20 sec  Forward Delay 15 sec

Interface      Role Sts Cost      Prio.Nbr Status
-----
Gi3/8          Root FWD 20000    128.136 P2p
Po1            Desg FWD 20000    128.833 P2p
```

The VLAN number can be found from the port, because ports involved in the loop were established in previous steps. If the ports in question are trunks, often all VLANs on the trunk are involved. If this is not the case (for example, if it appears that the loop has happened on a single VLAN) then you can try to issue the **show interfaces | include L2|line|broadcast** command (only on Supervisor 2 and later engines on Catalyst 6500/6000 series switches, because Supervisor 1 does not provide per-VLAN switching statistics). Look at VLAN interfaces only. The VLAN with the highest number of switched packets is often the one where the loop occurred:

```
<#root>
cat#
show interface | include L2|line|broadcast
```

```

Vlan1 is up, line protocol is up
  L2 Switched: ucast: 653704527 pkt, 124614363025 bytes - mcast:
    23036247 pkt, 1748707536 bytes
    Received 23201637 broadcasts, 0 runts, 0 giants, 0 throttles

Vlan10 is up, line protocol is up
  L2 Switched: ucast: 2510912 pkt, 137067402 bytes - mcast:
    41608705 pkt, 1931758378 bytes
    Received 1321246 broadcasts, 0 runts, 0 giants, 0 throttles
Vlan11 is up, line protocol is up
  L2 Switched: ucast: 73125 pkt, 2242976 bytes - mcast:
    3191097 pkt, 173652249 bytes
    Received 1440503 broadcasts, 0 runts, 0 giants, 0 throttles
Vlan100 is up, line protocol is up
  L2 Switched: ucast: 458110 pkt, 21858256 bytes - mcast:
    64534391 pkt, 2977052824 bytes
    Received 1176671 broadcasts, 0 runts, 0 giants, 0 throttles
Vlan101 is up, line protocol is up
  L2 Switched: ucast: 70649 pkt, 2124024 bytes - mcast:
    2175964 pkt, 108413700 bytes
    Received 1104890 broadcasts, 0 runts, 0 giants, 0 throttles

```

In this example, VLAN 1 accounts for the highest number of broadcasts and L2-switched traffic. Ensure that the root port is correctly identified.

The root port must have the lowest cost to the root bridge (sometimes one path is shorter in terms of hops but longer in terms of cost, as low-speed ports have higher costs). To determine which port is considered the root for a given VLAN, issue the **show spanning-tree vlan** command:

```

<#root>
cat#
show spanning-tree vlan 333

MST03
  Spanning tree enabled protocol mstp
  Root ID    Priority    32771
            Address    0050.14bb.6000
            Cost      20000

Port      136 (GigabitEthernet3/8)
          Hello Time  2 sec  Max Age 20 sec  Forward Delay 15 sec

  Bridge ID Priority    32771 (priority 32768 sys-id-ext 3)
  Address    00d0.003f.8800
  Hello Time 2 sec  Max Age 20 sec  Forward Delay 15 sec

Interface      Role Sts Cost      Prio.Nbr Status
-----
Gi3/8          Root FWD 20000    128.136 P2p
Po1            Desg FWD 20000    128.833 P2p

```

Ensure that the BPDUs are received regularly on the root port and on ports that are supposed to block.

BPDUs are sent by the root bridge at every hello interval (two seconds by default). Non-root bridges receive, process, modify, and propagate the BPDUs that are received from the root. Issue the **show spanning-tree interface interface detail** command to see if the BPDUs are received:

```
<#root>
```

```
cat#
```

```
show spanning-tree interface g3/2 detail
```

```
Port 130 (GigabitEthernet3/2) of MST00 is backup blocking
  Port path cost 20000, Port priority 128, Port Identifier 128.130.
  Designated root has priority 0, address 0007.4f1c.e847
  Designated bridge has priority 32768, address 00d0.003f.8800
  Designated port id is 128.129, designated path cost 2000019
  Timers: message age 4, forward delay 0, hold 0
```

```
Number of transitions to forwarding state: 0
```

```
  Link type is point-to-point by default, Internal
  Loop guard is enabled by default on the port
  BPDU: sent 3,
```

```
received 53
```

```
cat#
```

```
show spanning-tree interface g3/2 detail
```

```
Port 130 (GigabitEthernet3/2) of MST00 is backup blocking
  Port path cost 20000, Port priority 128, Port Identifier 128.130.
  Designated root has priority 0, address 0007.4f1c.e847
  Designated bridge has priority 32768, address 00d0.003f.8800
  Designated port id is 128.129, designated path cost 2000019
  Timers: message age 5, forward delay 0, hold 0
  Number of transitions to forwarding state: 0
  Link type is point-to-point by default, Internal
  Loop guard is enabled by default on the port
  BPDU: sent 3,
```

```
received 54
```

 **Note:** One BPDU has been received between the two outputs of the command (the counter went from 53 to 54).

The counters shown are actually counters maintained by the STP process itself. This means that, if the receive counters incremented, not only was BPDU received by a physical port, but it was also received by the STP process. If the `received` BPDU counter does not increment on the port that is supposed to be the root alternate or backup port, then check whether if the port receives multicasts at all (BPDUs are sent as multicast). Issue the **show interface interface counters** command:

```
<#root>
```

```
cat#
```

```
show interface g3/2 counters
```

```
Port          InOctets  InUcastPkts
```

```
InMcastPkts
```

```
  InBcastPkts
```

```
Gi3/2          14873036      2
```

```
89387
```

```
0
```

```
Port          OutOctets  OutUcastPkts  OutMcastPkts  OutBcastPkts
```

```
Gi3/2          114365997      83776      732086      19
```

```
cat#
```

```
show interface g3/2 counters
```

```
Port          InOctets  InUcastPkts
```

```
InMcastPkts
```

```
  InBcastPkts
```

```
Gi3/2          14873677      2
```

```
89391
```

```
0
```

```
Port          OutOctets  OutUcastPkts  OutMcastPkts  OutBcastPkts
```

```
Gi3/2          114366106      83776      732087      19
```

A brief description for STP port roles can be found in the [Enhance STP with Loop Guard and BPDU Skew Detection](#) section of [Spanning-Tree Protocol Enhancements using Loop Guard and BPDU Skew Detection Features](#). If no BPDUs are received, check whether the port counts the errors. Issue the **show interface interface counters errors** command:

```
<#root>
```

```
cat#
```

```
show interface g4/3 counters errors
```

```
Port    Align-Err  FCS-Err  Xmit-Err  Rcv-Err  UnderSize  OutDiscards
```

```
Gi4/3      0          0         0         0         0          0
```

```
Port    Single-Col  Multi-Col  Late-Col  Excess-Col  Carri-Sen  Runts  Giants
```

```
Gi4/3      0          0         0         0         0         0      0
```

It is possible that the BPDUs are received by the physical port but still do not reach the STP process. If the commands used in the previous two examples show that some multicasts are received, and errors are not counted, then check whether the BPDUs are dropped at the STP process level. Issue the **remote command**

switch test spanning-tree process-stats command on the Catalyst 6500:

```
<#root>
cat#
remote command switch test spanning-tree process-stats

-----TX STATS-----
transmission rate/sec      = 2
paks transmitted           = 5011226
paks transmitted (opt)     = 0
opt chunk alloc failures  = 0
max opt chunk allocated    = 0
-----RX STATS-----

receive rate/sec           = 1

paks received at stp isr   = 3947627
paks queued at stp isr    = 3947627

paks dropped at stp isr    = 0
drop rate/sec             = 0

paks dequeued at stp proc  = 3947627
paks waiting in queue     = 0
queue depth               = 7(max) 12288(total)
-----PROCESSING STATS-----
queue wait time (in ms)   = 0(avg) 540(max)
processing time (in ms)   = 0(avg) 4(max)
proc switch count        = 100
add vlan ports           = 20
time since last clearing  = 2087269 sec
```

The command used in this example displays the STP process statistics. It is important to verify that the drop counters do not increase and that received packets do increase. If received packets are not increased but the physical port does receive multicasts, verify that the packets are received by the switch in-band interface (the interface of the CPU). Issue the **remote command switch show ibc | i rx_input** command on the Catalyst 6500/6000:

```
<#root>
cat#
remote command switch show ibc | i rx_input

rx_inputs=
5626468
, rx_cumbytes=859971138
cat#
remote command switch show ibc | i rx_input
```

```
rx_inputs=
5626471
, rx_cumbytes=859971539
```

This example shows that, between the outputs, the in-band port has received 23 packets.

 **Note:** These 23 packets are not only BPDU packets; this is a global counter for all packets received by the in-band port.

If there is no indication that BPDUs are dropped on the local switch or port, you must move to the switch on the other side of the link and verify whether that switch sends the BPDUs. Check to see if the BPDUs are sent regularly on non-root, designated ports. If the port role concurs, the port sends BPDUs, but the neighbor does not receive them. Check whether BPDUs are sent. Issue the **show spanning-tree interface interface detail** command:

```
<#root>
cat#
show spanning-tree interface g3/1 detail

Port 129 (GigabitEthernet3/1) of MST00 is
designated
forwarding
  Port path cost 20000, Port priority 128, Port Identifier 128.129.
  Designated root has priority 0, address 0007.4f1c.e847
  Designated bridge has priority 32768, address 00d0.003f.8800
  Designated port id is 128.129, designated path cost 2000019
  Timers: message age 0, forward delay 0, hold 0
  Number of transitions to forwarding state: 0
  Link type is point-to-point by default, Internal
  Loop guard is enabled by default on the port

BPDUs: sent 1774
, received 1

cat#
show spanning-tree interface g3/1 detail

Port 129 (GigabitEthernet3/1) of MST00 is
designated
forwarding
  Port path cost 20000, Port priority 128, Port Identifier 128.129.
  Designated root has priority 0, address 0007.4f1c.e847
  Designated bridge has priority 32768, address 00d0.003f.8800
  Designated port id is 128.129, designated path cost 2000019
  Timers: message age 0, forward delay 0, hold 0
```

Number of transitions to forwarding state: 0
Link type is point-to-point by default, Internal
Loop guard is enabled by default on the port

BPDUs: sent 1776

, received 1

In this example, two BPDUs are sent out between the outputs.

 **Note:** The STP process maintains the BPDUs: sent counter. This means that the counter indicates that the BPDUs were sent toward the physical port and is sent out. Check whether the port counters increase for transmitted multicast packets. Issue the **show interface interface counters** command. This can help determine the BPDUs traffic flow.

```
<#root>
```

```
cat#
```

```
show interface g3/1 counters
```

With all of these steps, the idea is to find the switch or link where BPDUs are not received, sent, or processed. It is possible that the STP has calculated the correct state for the port, but due to a control plane

issue, it is unable to set this state on the forwarding hardware. A loop can be created if the port is not blocked at the hardware level. If you think this is an issue in your network, contact [Cisco Technical Support](#) for further assistance.

5. Restore the Redundancy

Once the device or link that causes the loop is found, this device must be isolated from the network, or the issue must be resolved (such as replace the fibre or GBIC). The redundant links, disconnected in Step 3, must be restored.

It is important to not manipulate the device or link that causes the loop, because many conditions that lead to a loop is transient, intermittent, and unstable. This means that, if the condition is cleared in or after investigation, the condition does not occur for a while does or not occur at all. The condition must be recorded so that the [Cisco Technical Support](#) can investigate it further. It is important that you collect information about the condition before you reset the switches. If a condition is gone, it is impossible to determine the root cause of the loop. If you collect the information, you ensure that this issue does not cause the loop again. For more information, refer to the [Securing the Network Against Forwarding Loops](#).

Investigate Topology Changes

The role of the Topology Change (TC) mechanism is to correct L2 forwarding tables after the topology has changed. This is necessary to avoid a connectivity outage because MAC addresses previously accessible through particular ports can change and become accessible through different ports. TC shortens the forwarding table age on all switches in the VLAN where the TC occurs. So, if the address is not relearned, it ages out and flooding occurs to ensure packets reach the destination MAC address.

TC is triggered by the change of a port's STP state to or from the STP forwarding state. After TC, even if the particular destination MAC address has aged out, flooding not continue for long. The address is relearned by the first packet that comes from the host whose MAC address has been aged out. The issue can arise when TC occur repeatedly, with short intervals. The switches are constantly fast aging their forwarding tables, so flooding can be nearly constant.

 **Note:** With Rapid STP or Multiple STP (IEEE 802.1w and IEEE 802.1s), TC is triggered by a change of the port's state to forwarding, as well as the role change from designated to root. With Rapid STP, the L2 forwarding table is immediately flushed, as opposed to 802.1d, which shortens the aging time. The immediate flushing of the forwarding table restores connectivity faster, but can cause more flooding

TC is a rare event in a well-configured network. When a link on a switch port goes up or down, there is eventually a TC, once the STP state of the port is changed to or from forwarding. When the port is flapping, this would cause repetitive TCs and flooding.

Ports with the STP portfast feature enabled cannot cause TCs when they go to or from the forwarding state. The configuration of portfast on all end-device ports (such as printers, PCs, and servers) can limit TCs to a low amount and is highly recommended.

If there are repetitive TCs on the network, you must identify the source of these TCs and take action to reduce them, to bring the flooding to a minimum.

With 802.1d, STP information about a TC event is propagated among the bridges through a TC Notification (TCN), which is a special type of BPDU. If you follow the ports that receive TCN BPDUs, you can find the device that originated the TCs.

Find the Cause of the Flooding

You can determine that there is flooding from slow performance, packet drops on links that are not supposed to be congested, and the packet analyzer shows multiple unicast packets to the same destination that is not on the local segment. For more information on unicast flooding, refer to [Unicast Flooding in Switched Campus Networks](#).

On a Catalyst 6500/6000 that runs Cisco IOS software, you can check the forwarding engine counter (only on the Supervisor 2 engine) to estimate the amount of flooding. Issue the **remote command switch show earl statistics | i MISS_DA|ST_FR** command:

```
<#root>

cat#

remote command switch show earl statistics | i MISS_DA|ST_FR

          ST_MISS_DA      =          18          530308834
          ST_FRMS         =          97          969084354

cat#

remote command switch show earl statistics | i MISS_DA|ST_FR

          ST_MISS_DA      =           4          530308838
          ST_FRMS         =          23          969084377
```

In this example, the first column shows the change since the last time this command was executed, and the second column shows the cumulative value since the last reboot. The first line shows the amount of flooded frames, and the second line shows the amount of processed frames. If the two values are close together, or the first value increases at a high rate, it can that the switch is flooding traffic. However, this can only be used in conjunction with other ways to verify flooding, as the counters are not granular. There is one counter per switch, not per port or VLAN. It is normal to see some flooding packets, as the switch can always flood if the destination MAC address is not in the forwarding table. This can be the case when the switch receives a packet with a destination address that has not yet been learned.

Find the Source of the TCs

If the VLAN number is known for the VLAN where excessive flooding is occurs, check the STP counters to see if the number of TCs is high or regularly increments. Issue the **show spanning-tree vlan vlan-id detail** command (in this example, VLAN 1 is used):

```
<#root>

cat#

show spanning-tree vlan 1 detail

VLAN0001 is executing the ieee compatible Spanning Tree protocol
  Bridge Identifier has priority 32768, sysid 1, address 0007.0e8f.04c0
  Configured hello time 2, max age 20, forward delay 15
  Current root has priority 0, address 0007.4f1c.e847
```

```
Root port is 65 (GigabitEthernet2/1), cost of root path is 119
Topology change flag not set, detected flag not set
```

```
Number of topology changes 1 last change occurred 00:00:35 ago
from GigabitEthernet1/1
```

```
Times: hold 1, topology change 35, notification 2
hello 2, max age 20, forward delay 15
Timers: hello 0, topology change 0, notification 0, aging 300
```

If the VLAN number is not known, you can use the packet analyzer or check the TC counters for all VLANs.

Take Steps to Prevent Excessive TCs

You can monitor the number of topology changes counter to see if it regularly increases. Then, move to the bridge that is connected to the port that is shown, to receive the last TC (in the previous example, port GigabitEthernet1/1) and see from where the TC came for that bridge. This process must be repeated until the end-station port without STP portfast enabled is found, or until the flapping link is found that needs to be fixed. The entire procedure needs to be repeated if TCs come from other sources. If the link belongs to an end-host, you can configure the portfast feature to prevent the generation of TCs.

 **Note:** In the Cisco IOS software STP implementation, the counter for TCs can only increment if a TCN BPDU is received by a port in a VLAN. If a normal configuration BPDU with a set TC flag is received, then the TC counter is not incremented. This means that, if you suspect a TC to be the reason for flooding, start to track down the sources for the TC from the STP root bridge in that VLAN. It can have the most accurate information about the number and source of the TCs.

Troubleshoot Convergence Time Related Issues

There are situations when the actual operation of STP does not match the expected behavior. These are the two most frequent issues:

- STP convergence or reconvergence takes longer than expected.
- The topology result is different than expected.

Most often, these are the reasons for this behavior:

- A mismatch between the real and documented topology.
- Misconfiguration, such as an inconsistent configuration of STP timers, a STP diameter that increases, or portfast misconfiguration.
- Overloaded switch CPU during convergence or reconvergence.
- Software defect.

As mentioned earlier, this document can only provide general guidelines for troubleshooting, due to the wide variety of issues that could affect STP. To understand why the convergence takes longer than expected, look at the sequence of STP events to find out what happens and in what order. Because the STP implementation in Cisco IOS software does not log outcomes (except for specific events, such as port

inconsistencies), you can use Cisco IOS software to debug STP for a clearer view. For STP, with a Catalyst 6500/6000 that runs Cisco IOS software, processing is done on the Switch Processor (SP) (or Supervisor), so the debugs need to be enabled on the SP. For Cisco IOS software bridge groups, processing is done on the Route Processor (RP), so the debugs need to be enabled on the RP (MSFC).

Use STP Debug Commands

Many STP debug commands are intended for development engineering use. They do not provide any output that is meaningful to someone without detailed knowledge of the STP implementation in Cisco IOS software. Some debugs can provide output which is instantly readable, such as port state changes, role changes, events such as TCs, and a dump of received and transmitted BPDUs. This section does not provide a complete description of all of the debugs, but rather briefly introduces the most frequently used ones.

 **Note:** When you use debug commands, enable the minimum necessary debugs. If real-time debugs are not needed, record the output to the log rather than print it to the console. Excessive debugs can overload the CPU and disrupt switch operation.

To direct debug output to the log instead of to the console or to Telnet sessions, issue the **logging console informational** and **no logging monitor** commands in global configuration mode. To see the general events log, issue the **debug spanning-tree event** command for Per VLAN Spanning-Tree (PVST) and Rapid-PVST. This is the first debug that gives information about what happened with the STP. In Multiple Spanning-Tree (MST) mode, it does not work to issue the **debug spanning-tree event** command. Therefore, issue the **debug spanning-tree mstp roles** command to see the port role changes. To see the port STP state changes, issue the **debug spanning-tree switch state** command together with the **debug pm vp** command:

```
<#root>
```

```
cat-sp#
```

```
debug spanning-tree switch state
```

```
Spanning Tree Port state changes debugging is on
```

```
cat-sp#
```

```

To understand why STP behaves in a certain way, it is often useful to see the BPDUs that are received and sent by the switch:

```
<#root>
```

```
cat-sp#
```

```
debug spanning-tree bpdud receive
```

```
Spanning Tree BPDUD Received debugging is on
```

```
Nov 6 11:44:27: SP: STP: VLAN1 rx BPDUD: config protocol = ieee,  
packet from GigabitEthernet2/1 , linktype IEEE_SPANNING ,  
enctype 2, encsize 17
```

```
Nov 6 11:44:27: SP: STP: enc 01 80 C2 00 00 00 00 06 52 5F 0E 50 00 26 42 42 03
```

```
Nov 6 11:44:27: SP: STP: Data 000000000000000000074F1CE8470000001380480006525F0E4  
080100100140002000F00
```

```
Nov 6 11:44:27: SP: STP: VLAN1 Gi2/1:0000 00 00 00 000000074F1CE847 00000013  
80480006525F0E40 8010 0100 1400 0200 0F00
```

This debug works for PVST, Rapid-PVST, and MST modes; but it does not decode the contents of the BPDUs. However, you can use it to ensure that BPDUs are received. To see the contents of the BPDUD, issue the **debug spanning-tree switch rx decode** command together with the **debug spanning-tree switch rx process** command for PVST and Rapid-PVST. Issue the **debug spanning-tree mstp bpdud-rx** command to see the contents of the BPDUD for MST:

```
<#root>
```

```
cat-sp#
```

```
debug spanning-tree switch rx decode
```

```
Spanning Tree Switch Shim decode received packets debugging is on
```

```
cat-sp#
```

```
debug spanning-tree switch rx process
```

```
Spanning Tree Switch Shim process receive bpdud debugging is on
```

```
Nov 6 12:23:20: SP: STP SW: PROC RX: 0180.c200.0000<-0006.525f.0e50 type/len 0026
```

```
Nov 6 12:23:20: SP: encap SAP linktype ieee-st vlan 1 len 52 on v1 Gi2/1
```

```

 **Note:** For Cisco IOS Software Release 12.1.13E and later, conditional debugs for STP are supported. This means that you can debug BPDUs that are received or transmitted on a per-port or per-VLAN basis.

Issue the **debug condition vlan vlan_num or debug condition interface interface** commands, to limit the scope of the debug output to per-interface or per-VLAN.

Secure the Network Against Forwarding Loops

Cisco has developed a number of features and enhancements to protect the networks against forwarding loops when a STP cannot manage certain failures.

When you troubleshoot the STP, it helps to isolate and possibly find the cause for a particular failure, while the implementation of these enhancements is the only way to secure the network against forwarding loops.

These are methods to protect your network against forwarding loops:

1. Enable Unidirectional Link Detection (UDLD) on all Switch-to-Switch Links

For more information on UDLD, refer to [Understanding and Configuring the Unidirectional Link Detection Protocol Feature](#).

2. Enable Loop Guard on all Switches

For more information on Loop Guard, refer to [Spanning-Tree Protocol Enhancements using Loop Guard and BPDU Skew Detection Features](#).

When enabled, UDLD and Loop Guard eliminate the majority of causes of forwarding loops. Rather than create a forwarding loop, the defective link (or all links dependent on the defective hardware) shut down or are blocked.

 **Note:** While these two features appear somewhat redundant, each has its unique capabilities. Therefore, use both features at the same time to provide the highest level of protection. For a detailed comparison of UDLD and Loop Guard, refer to [Loop Guard vs. Unidirectional Link Detection](#).

There are different opinions about whether you have to use aggressive or normal UDLD. The aggressive UDLD cannot provide more protection against loops compared to normal mode UDLD. Aggressive UDLD detects port-stuck scenarios (when the link is up, but there are no associated traffic blackholes). The downside of this added functionality is that aggressive UDLD can potentially disable links when no consistent failure is present. Often people confuse the modification of the UDLDhe110interval with the aggressive UDLD feature. This is incorrect. Timers can be modified in both UDLD modes.

 **Note:** In rare cases, aggressive UDLD can shut down all of the uplink ports, which essentially isolates the switch from the rest of the network. For example, this could happen when both upstream switches experience extremely high CPU utilization and aggressive mode UDLD is used. Therefore, it is recommended that you configure times outs that cannot erode, if the switch does not have out-of-band management in place.

3. Enable Portfast on all End-Station Ports

You must enable portfast to limit the amount of TCs and subsequent flooding, which can affect the performance of the network. Only use this command with ports that connect to end stations. Otherwise, an accidental topology loop can cause a data-packet loop and disrupt the switch and network operation.

 **Caution:** Exercise caution when you use the **no spanning-tree portfast** command. This command only removes any port specific portfast commands. This command implicitly enables portfast if you define the **spanning-tree portfast default** command in global configuration mode and if the port is not a trunk port. If you do not configure portfast globally, the **no spanning-tree portfast** command is equivalent to the **spanning-tree portfast disable** command.

4. Set EtherChannels to Desirable Mode on Both Sides (where supported) and Non-silent Option

Desirable mode can enable Port Aggregation Protocol (PAgP) to ensure runtime consistency between the channeling peers. This gives an additional degree of protection against loops, especially during channel reconfigurations (such as when links join or leave the channel, and link failure detection). There is a built-in Channel Misconfiguration Guard, which is enabled by default, and which prevents forwarding loops due to channel misconfiguration or other conditions. For more information on this feature, refer to [Understanding EtherChannel Inconsistency Detection](#).

5. Do Not Disable Auto-Negotiation (if supported) on Switch-to-Switch Links

Auto-negotiation mechanisms can convey remote fault information, which is the quickest way to detect failure at the remote side. If failure be detected at the remote side, the local side brings down the link even if the link gets pulses. Compared to high-level detection mechanisms such as UDLD, auto-negotiation is extremely fast (within microseconds) but lacks the end-to-end coverage of UDLD (such as the entire datapath: CPU—forwarding logic—port1—port2—forwarding logic—CPU versus port1—port2). Aggressive UDLD mode provides similar functionality to that of auto-negotiation with regards to failure detection. When negotiation is supported on both sides of the link, there is no need to enable aggressive mode UDLD.

6. Use Caution when You Tune the STP Timers

STP timers are dependent on each other and on the network topology. STP does not work correctly with arbitrary modifications made to the timers. For more information about STP timers, refer to [Understanding and Tuning Spanning Tree Protocol Timers](#).

7. If Denial of Service Attacks is Possible, Secure the Network STP Perimeter with Root Guard

Root Guard and BPDU Guard allow you to secure STP against influence from the outside. If such an attack is a possibility, Root Guard and BPDU Guard must be used to protect the network. For more information on Root Guard and BPDU Guard, refer to these documents:

- [Spanning-Tree Protocol Root Guard Enhancement](#)
- [Spanning Tree Portfast BPDU Guard Enhancement](#)

8. Enable BPDU Guard on Portfast-Enabled Ports, to Prevent STP from the Effect of Unauthorized Network Devices (such as hubs, switches, and bridging routers) that are Connected to the Ports

If you configure Root Guard correctly, it prevents the STP from influence from the outside. If BPDU Guard is enabled, it shuts down the ports that receive any BPDUs. This is useful to investigate incidents, because BPDU Guard produces the syslog message and shuts down the port. If Root or BPDU Guards do not prevent short-cycle loops, then two fast-enabled ports connect directly or through the hub.

9. Avoid User Traffic on the Management VLAN

The Management VLAN is Contained to a Building Block, not the Entire Network.

The switch management interface receives broadcast packets on the management VLAN. If excessive broadcasts occur (such as a broadcast storm or a malfunctioning application), the switch CPU can become overloaded, which could possibly distort STP operation.

10. A Predictable (hardcoded) STP Root and Backup STP Root Placement

The STP root and backup STP root must be configured so that convergence, in the case of failures, occurs in a predictable way and builds optimal topology in every scenario. Do not leave the STP priority at the default value, to prevent unpredictable root switch selection.
